Abstract

This paper tackles a complex version of the Job Shop Scheduling Problem (JSSP) that involves both the possibility to select alternative resources to activities and the presence of sequence dependent setup times. The proposed solving strategy is a variant of the known Iterative Flattening Search (IFS) metaheuristic. This work presents the following contributions: (1) a new constraint-based solving procedure produced by means of enhancing a previous JSSP-solving version of the same metaheuristic; (2) a new version of both the variable and value ordering heuristics, based on temporal flexibility, that capture the relevant features of the extended scheduling problem (i.e., the flexibility in the assignment of resources to activities, and the sequence dependent setup times); (3) a new relaxation strategy based on the random selection of the activities that are closer to the critical path of the solution, as opposed to the original approach based on a fully random relaxation. The performance of the proposed algorithm are tested on a new benchmark set produced as an extension of an existing well-known testset for the Flexible Job Shop Scheduling Problem by adding sequence dependent setup times to each original testset's instance, and the behavior of the old and new relaxation strategies are compared.

Introduction

This paper describes an iterative improvement approach to solve job-shop scheduling problems involving both *sequence dependent* setup-times and the possibility of selecting *alternative routes* among the available machines. Over the last years there has been an increasing interest in solving scheduling problems involving both setup-times and flexible shop environments (Allahverdi and Soroush 2008; Allahverdi et al. 2008). This fact stems mainly from the observation that in various real-world industry or service environments there are tremendous savings when setup times are explicitly considered in scheduling decisions. In addition, the possibility of selecting alternative routes among the available machines is motivated by interest in developing Flexible Manufacturing Systems (FMS) (Sethi and Sethi 1990) able to use multiple machines to perform the same operation on a job's part, as well as to absorb large-scale changes, such as in volume, capacity, or capability.

The proposed problem, called in the rest of the paper Flexible Job Shop Scheduling Problem with Sequence Dependent Setup Times (SDST-FJSSP) is a generalization of

the classical Job Shop Scheduling Problem (JSSP) where each activity requires a single machine and there are no setup-times. This problem is more difficult than the classical JSSP (which is itself *NP-hard*), since it is not just a sequencing problem; in addition to deciding how to sequence activities that require the same machine (involving sequence-dependent setup-times), it is also necessary to choose a *routing policy*, i.e., deciding which machine will process each activity. The objective remains that of minimizing *makespan*.

Despite this problem is often met in real manufacturing systems, not many papers consider both sequence dependent setup-times in flexible job-shop environments. On the other hand, a richer literature is available when setup-times and flexible job-shop environments are considered separately. In particular, on the side of setup-times a first reference work is (Brucker and Thiele 1996), which relies on an earlier proposal presented in (Brucker, Jurisch, and Sievers 1994). More recent works are (Vela, Varela, and González 2009) and (González, Vela, and Varela 2009), which propose effective heuristic procedures based on genetic algorithms and local search. In these works, the introduced local search procedures extend an approach originally proposed by (Nowicki and Smutnicki 2005) for the classical job-shop scheduling problem to the setup times case. A last noteworthy work is (Balas, Simonetti, and Vazacopoulos 2008), which extends the well-known *shifting bottleneck* procedure (Adams, Balas, and Zawack 1988) to the setup-time case. Both (Balas, Simonetti, and Vazacopoulos 2008) and (Vela, Varela, and González 2009) have produced reference results on a previously studied benchmark set of JSSP with sequence dependent setup-times problems initially proposed by (Brucker and Thiele 1996). About the Flexible Job Shop Scheduling FJSSP an effective synthesis of the existing solving approaches is proposed in (Hmida et al. 2010). The core set of procedures which generate the best results include the genetic algorithm (GA) proposed in (Gao, Sun, and Gen 2008), the tabu search (TS) approach of (Mastrolilli and Gambardella 2000) and the discrepancy-based method, called climbing depth-bound discrepancy search (CDDS), defined in (Hmida et al. 2010). Among the papers dealing with both sequence dependent setup times and flexible shop environments there is the work (Rossi and Dini 2007), which considers a shop type composed of pools of identical ma-

chines as well as two types of setup times: one modeling the transportation times between different machines (sequence dependent) and the other one modeling the required reconfiguration times (not sequence dependent) on the machines. The other work (Ruiz and Maroto 2006) considers a flowshop environment with multi-purpose machines, such that each stage of a job can be processed by a set of unrelated machines (the processing times of the jobs depend on the machine they are assigned to). (Vallada and Ruiz 2011) considers a problem similar to the previous one, where the jobs are composed by a single step, but setup-times are both sequence and machine dependent. Finally, (Valls, Perez, and Quintanilla 1998) considers a job-shop problem with parallel identical machines, release times and due dates but sequence independent setup-times.

This paper focuses on a family of solving techniques referred to as Iterative Flattening Search (IFS). IFS was first introduced in (Cesta, Oddi, and Smith 2000) as a scalable procedure for solving multi-capacity scheduling problems. IFS is an iterative improvement heuristic designed to minimize schedule makespan. Given an initial solution, IFS iteratively applies two-steps: (1) a subset of solving decisions are randomly retracted from a current solution (*relaxation-step*); (2) a new solution is then incrementally recomputed (*flattening-step*). Extensions to the original IFS procedure were made in two subsequent works (Michel and Van Hentenryck 2004; Godard, Laborie, and Nuijten 2005) and more recently (Oddi et al. 2010) have performed a systematic study aimed at evaluating the effectiveness of single *component strategies* within the same uniform software framework. The IFS variant that we propose relies on a *core constraint-based search procedure* as its solver. This procedure is an extension of the SP-PCP procedure proposed in (Oddi and Smith 1997). SP-PCP generates consistent orderings of activities requiring the same resource by imposing precedence constraints on a temporally feasible solution, using *variable* and *value* ordering heuristics that discriminate on the basis of temporal flexibility to guide the search. We extend both the procedure and these heuristics to take into account both sequence dependent setup-times and flexibility in machine selection. To provide a basis for embedding this core solver within an IFS optimization framework, we also specify an original relaxation strategy based on the idea of randomly breaking the execution orders of the activities on the machines with a activity selection criteria based on their *proximity* to the solution's critical path.

The paper is organized as follows. The first two sections define the SDST-FJSSP problem and its CSP representation. The main contribution of the work is given by two further sections which respectively describes the core constraint-based search procedure and the definition of the IFS meta-heuristic. An experimental section describes the performance of our algorithm on a set of benchmark problems and explains the most interesting results. Some conclusions end the paper.

The Scheduling Problem

The SDST-FJSSP entails synchronizing the use of a set of machines (or resources) $R = \{r_1, \dots, r_m\}$ to perform a set

of n activities $A = \{a_1, \dots, a_n\}$ over time. The set of activities is partitioned into a set of n_j jobs $\mathcal{J} = \{J_1, \dots, J_{n_j}\}$. The processing of a job J_k requires the execution of a strict sequence of n_k activities $a_i \in J_k$ and cannot be modified. All jobs are released at time 0. Each activity a_i requires the exclusive use of a *single resource* r_i for its entire duration chosen among a *set of available resources* $R_i \subseteq R$. No *pre-emption* is allowed. Each machine is available at time 0 and can process more than one operation of a given job J_k (*recirculation* is allowed). The processing time p_{ir} of each activity a_i depends on the selected machine $r \in R_i$, such that $e_i - s_i = p_{ir}$, where the variables s_i and e_i represent the start and end time of a_i . Moreover, for each resource r , the value st_{ij}^r represents the setup time between two generic activities a_i and a_j (a_j is scheduled immediately after a_i) requiring the same resource r , such that $e_i + st_{ij}^r \leq s_j$. As is traditionally assumed in the literature, the setup times st_{ij}^r satisfy the so-called *triangular inequality* (see (Brucker and Thiele 1996; Artigues and Feillet 2008)). The triangle inequality states that, for any three activities a_i, a_j, a_k requiring the same resource, the inequality $st_{ij}^r \leq st_{ik}^r + st_{kj}^r$ holds. A *solution* $S = \{(\bar{s}_1, \bar{r}_1), (\bar{s}_2, \bar{r}_2), \dots, (\bar{s}_n, \bar{r}_n)\}$ is a set of pairs (\bar{s}_i, \bar{r}_i) , where \bar{s}_i is the assigned start-time of a_i , \bar{r}_i is the selected resource for a_i and all the above constraints are satisfied. Let C_k be the completion time for the job J_k , the *makespan* is the value $C_{max} = \max_{1 \leq k \leq n_j} \{C_k\}$. An *optimal solution* S^* is a solution S with the minimum value of C_{max} . The SDST-FJSSP is *NP-hard* since it is an extension of the JSSP problem (Garey and Johnson 1979).

A CSP Representation

There are different ways to model the problem as a *Constraint Satisfaction Problem* (CSP) (Montanari 1974), we use an approach similar to (Oddi and Smith 1997). In particular, we focus on *assigning resources to activities*, a distinguishing aspect of SDST-FJSSP and on *establishing sequence dependent setup time constraints* between pairs of activities that require the same resource, so as to eliminate all possible conflicts in the resource usage.

Let $G(A_G, J, X)$ be a graph where the set of vertices A_G contains all the activities of the problem together with two dummy activities, a_0 and a_{n+1} , respectively representing the beginning (reference) and the end (horizon) of the schedule. Each activity a_i is labelled with the set of available resource choices R_i . J is a set of directed edges (a_i, a_j) representing the precedence constraints among the activities (job precedences constraints) and are labelled with the set of processing times p_{ir} ($r \in R_i$) of the edge's source activity a_i . The set of undirected edges X represents the *disjunctive constraints* among the activities requiring the same resource r ; there is an edge for each pair of activities a_i and a_j requiring the same resource r ($R_i = R_j = \{r\}$) and the related label represents the set of possible ordering between a_i and a_j : $a_i \preceq a_j$ or $a_j \preceq a_i$. Hence, in CSP terms, there are *two sets of decision variables*: (1) a variable x_i is defined for each activity a_i to select one resource for its execution, the domain of x_i is the set of available resource R_i ; (2) A variable o_{ijr} is defined for each pair of activities a_i and a_j

requiring the same resource r ($x_i = x_j = r$), which can take one of two values $a_i \preceq a_j$ or $a_j \preceq a_i$. It is worth noting that in considering either ordering we have to take into account the presence of sequence dependent setup times, which must be included when an activity a_i is executed on the same resource *before* another activity a_j . As we will see in the next sections, the previous decisions for o_{ijr} can be represented as the following two temporal constraints: $e_i + st_{ij}^r \leq s_j$ (i.e. $a_i \preceq a_j$) or $e_j + st_{ji}^r \leq s_i$ (i.e. $a_j \preceq a_i$).

To support the search for a consistent assignment to the set of decision variables x_i and o_{ijr} , for any SDST-FJSSP we define the directed graph $G_d(V, E)$, called *distance graph*, which is an extended version of the graph $G(A_G, J, X)$. The set of nodes V represents time points, where tp_0 is the *origin* time point (the reference point of the problem), while for each activity a_i , s_i and e_i represent its start and end time points respectively. The set of edges E represents all the imposed temporal constraints, i.e., precedences and durations. In particular, for each activity a_i we impose the interval duration constraint $e_i - s_i \in [p_i^{min}, p_i^{max}]$, such that p_i^{min} (p_i^{max}) is the minimum (maximum) processing time according to the set of available resources R_i . Given two time points tp_i and tp_j , all the constraints have the form $a \leq tp_j - tp_i \leq b$, and for each constraint specified in the SDST-FJSSP instance there are two weighted edges in the graph $G_d(V, E)$; the first one is directed from tp_i to tp_j with weight b and the second one is directed from tp_j to tp_i with weight $-a$. The graph $G_d(V, E)$ corresponds to a *Simple Temporal Problem* (STP) and its consistency can be efficiently determined via shortest path computations; the problem is consistent if and only if no closed paths with negative length (or negative cycles) are contained in the graph G_d (Dechter, Meiri, and Pearl 1991). Thus, a search for a solution to a SDST-FJSSP instance *can proceed by repeatedly adding new precedence constraints into $G_d(V, E)$ and recomputing shortest path lengths to confirm that $G_d(V, E)$ remains consistent.*

A solution S is given as an affine graph $G_S(A_G, J, X_S)$, such that each undirected edge (a_i, a_j) in X is replaced with a directed edge representing one of the possible orderings between a_i and a_j : $a_i \preceq a_j$ or $a_j \preceq a_i$. In general the directed graph G_S represents a set of temporal solutions (S_1, S_2, \dots, S_n) that is, a set of assignments to the activities' start-times which are consistent with the set of imposed constraints X_S . Let $d(tp_i, tp_j)$ ($d(tp_j, tp_i)$) designate the shortest path length in graph $G_d(V, E)$ from node tp_i to node tp_j (from node tp_j to node tp_i); then, the constraint $-d(tp_j, tp_i) \leq tp_j - tp_i \leq d(tp_i, tp_j)$ is demonstrated to hold (Dechter, Meiri, and Pearl 1991). Hence, the interval $[lb_i, ub_i]$ of time values associated with a given time variable tp_i respect to the *reference* point tp_0 is computed on the graph G_d as the interval $[-d(tp_i, tp_0), d(tp_0, tp_i)]$. In particular, given a STP, the following two sets of value assignments $S_{lb} = \{-d(tp_1, tp_0), -d(tp_2, tp_0), \dots, -d(tp_n, tp_0)\}$ and $S_{ub} = \{d(tp_0, tp_1), d(tp_0, tp_2), \dots, d(tp_0, tp_n)\}$ to the STP variables tp_i represent the so-called *earliest-time solution* and *latest-time solution*, respectively.

Basic Constraint-based Search

The proposed procedure for solving instances of SDST-FJSSP integrates a Precedence Constraint Posting (PCP) one-shot search for generating sample solutions and an Iterative Flattening meta-heuristic that pursues optimization. The one-shot step, similarly to the SP-PCP scheduling procedure (Shortest Path-based Precedence Constraint Posting) proposed in (Oddi and Smith 1997), utilizes shortest path information in $G_d(V, E)$ to guide the search process. Shortest path information is used in a twofold fashion to enhance the search process: to propagate problem constraints and to define variable and value ordering heuristics.

Propagation Rules

The first way to exploit shortest path information is by introducing conditions to remove infeasible values from the domains of the decision variables x_i , representing the assignment of resources to activities. Namely, for each activity a_i we relax the disjunctive duration constraint into the interval constraint $e_i - s_i \in [p_i^{min}, p_i^{max}]$, such that p_i^{min} (p_i^{max}) is the minimum (maximum) processing time according to the set of available resources R_i (R_i is the domain of the decision variable x_i). As the search proceeds, as soon as the interval of distance between the start-time and the end-time of a_i $[-d(s_i, e_i), d(e_i, s_i)]$ is updated, the duration $p_{ir} \notin [-d(s_i, e_i), d(e_i, s_i)]$ is removed from the domain of x_i and a new interval $[p_i^{min}, p_i^{max}]$ is recomputed accordingly. In case of the domain of the decision variable x_i becomes *empty*, the search reaches a *failure* state.

The second way to exploit shortest path is by introducing new *Dominance Conditions* (which adapt those presented in (Oddi and Smith 1997) to the setup times case), through which problem constraints are *propagated* and mandatory decisions for promoting early pruning of alternatives are identified. The following concepts of *slack*(e_i, s_j) and *co-slack*(e_i, s_j) (complementary slack) play a central role in the definition of such new dominance conditions. Given two activities a_i, a_j and the related interval of distances $[-d(s_j, e_i), d(e_i, s_j)]$ ¹ and $[-d(s_i, e_j), d(e_j, s_i)]$ ² on the graph G_d , they are defined as follows:

- *slack*(e_i, s_j) = $d(e_i, s_j) - st_{ij}^r$ is the difference between the maximal distance $d(e_i, s_j)$ and the setup time st_{ij}^r . Hence, it provides a measure of the degree of *sequencing flexibility* between a_i and a_j ³ taking into account the setup time constraint $e_i + st_{ij}^r \leq s_j$. If *slack*(e_i, s_j) < 0, then the ordering $a_i \preceq a_j$ is not feasible.
- *co-slack*(e_i, s_j) = $-d(s_j, e_i) - st_{ij}^r$ is the difference between the minimum possible distance between a_i and a_j , $-d(s_j, e_i)$, and the setup time st_{ij}^r ; if *co-slack*(e_i, s_j) \geq 0, then there is no need to separate a_i and a_j , as the setup time constraint $e_i + st_{ij}^r \leq s_j$ is already satisfied.

¹Between the end-time e_i of a_i and the start-time s_j of a_j

²Between the end-time e_j of a_j and the start-time s_i of a_i

³Intuitively, the higher is the degree of *sequencing flexibility*, the larger is the set of feasible assignments to the start-times of a_i and a_j

For any pair of activities a_i and a_j that can **compete for the same resource** r ($R_i \cap R_j \neq \emptyset$), given the corresponding durations p_{ir} and p_{jr} , the Dominance Conditions, describing the four main possible cases of conflict, are defined as follows:

1. $slack(e_i, s_j) < 0 \wedge slack(e_j, s_i) < 0$
2. $slack(e_i, s_j) < 0 \wedge slack(e_j, s_i) \geq 0 \wedge co-slack(e_j, s_i) < 0$
3. $slack(e_i, s_j) \geq 0 \wedge slack(e_j, s_i) < 0 \wedge co-slack(e_i, s_j) < 0$
4. $slack(e_i, s_j) \geq 0 \wedge slack(e_j, s_i) \geq 0$

Condition 1 represents an *unresolvable conflict*. There is no way to order a_i and a_j taking into account the setup times st_{ij}^r and st_{ji}^r , without inducing a negative cycle in the graph $G_d(V, E)$. When Condition 1 is verified there are four different interesting sub-cases generated on the basis of the cardinality of the domain sets R_i and R_j .

- a. $|R_i| = |R_j| = 1$: the search has reached a *failure* state;
- b. $|R_i| = 1 \wedge |R_j| > 1$: the resource requirement r can be removed from R_j ;
- c. $|R_i| > 1 \wedge |R_j| = 1$: the resource requirement r can be removed from R_i ;
- d. $|R_i| > 1 \wedge |R_j| > 1$: the activities a_i and a_j cannot use the same resource r .

Conditions 2, and 3, alternatively, distinguish *uniquely resolvable conflicts*, i.e., there is only one feasible ordering of a_i and a_j when both the activities require r , and the decision of which constraint to post is thus unconditional. In the particular case where $|R_i| = |R_j| = 1$ the decision $a_j \preceq a_i$ is mandatory; if Condition 2 is verified, only $a_j \preceq a_i$ leaves $G_d(V, E)$ consistent. It is worth noting that the presence of the condition $co-slack(e_j, s_i) < 0$ entails that the minimal distance between the end time e_j and the start time s_i is shorter than the minimal required setup time st_{ji}^r ; hence, we still need to impose the constraint $e_j + st_{ji}^r \leq s_i$. In other words, the *co-slack* condition avoids the imposition of unnecessary precedence constraints for trivially solved conflicts. Condition 3 works similarly, and entails that only the $a_i \preceq a_j$ ordering is feasible. In case there is at least one activity with more than one resource option ($|R_i| > 1 \vee |R_j| > 1$), it is still possible to choose different resource assignments for a_i and a_j , and avoid posting a precedence constraint. Condition 3 works similarly, and entails that only the $a_i \preceq a_j$ ordering is feasible when $|R_i| = |R_j| = 1$.

Condition 4 designates a class of *resolvable conflicts* with more search options; in this case when $|R_i| = |R_j| = 1$ both orderings of a_i and a_j remain feasible, and it is therefore necessary to perform a *search decision*. When there is at least one activity a_i or a_j with more than one resource option ($|R_i| > 1 \vee |R_j| > 1$), then there is also the possibility of choosing different resource assignment to a_i and a_j , and avoid to post a precedence constraint.

Heuristic Analysis

Shortest path information in G_d can also be exploited to define *variable* and *value* ordering heuristics for the decision variables x_i and o_{ijr} in all cases where no mandatory decisions are deduced from the propagation phase. The idea

is to evaluate both types of decision variables (x_i and o_{ijr}) and select the one (independently of type) with the minimum heuristic evaluation. The selection of the variables is based on the *most constrained first* (MCF) principle and the selection of values follows the *least constraining value* (LCV) heuristic.

Ordering decision variables. We start to analyze the case of selecting an ordering decision variables o_{ijr} , under the hypothesis that both the activity a_i and a_j use the same resource $r \in R_i \cap R_j$. As stated above, in this context $slack(e_i, s_j)$ and $slack(e_j, s_i)$ provide measures of the degree of *sequencing flexibility* between a_i and a_j . More precisely, given a variable o_{ijr} , related to the pair (a_i, a_j) , its heuristic evaluation

$$VarEval(a_i, a_j) = \begin{cases} \min\left\{\frac{slack(e_i, s_j)}{\sqrt{S}}, \frac{slack(e_j, s_i)}{\sqrt{S}}\right\} : \\ \text{if } slack(e_i, s_j) \geq 0 \wedge slack(e_j, s_i) \geq 0 \\ slack(e_j, s_i) : \\ \text{if } slack(e_i, s_j) < 0 \wedge slack(e_j, s_i) \geq 0 \\ slack(e_i, s_j) : \\ \text{if } slack(e_i, s_j) \geq 0 \wedge slack(e_j, s_i) < 0 \end{cases}$$

where $S = \frac{\min\{slack(e_i, s_j), slack(e_j, s_i)\}}{\max\{slack(e_i, s_j), slack(e_j, s_i)\}}$ ⁴. The *variable* ordering heuristic attempts to focus first on the most constrained conflict (a_i, a_j) , that is, on the conflict with the least amount of temporal flexibility (i.e., the conflict that is closest to previous Condition 1.a).

As opposed to variable ordering, the *value* ordering heuristic attempts to resolve the selected conflict (a_i, a_j) by simply choosing the activity pair sequencing that retains the highest amount of temporal flexibility (least constrained value). Specifically, $a_i \preceq a_j$ is selected if $slack(e_i, s_j) > slack(e_j, s_i)$ and $a_j \preceq a_i$ is selected otherwise.

Resource decision variables. Decision variables x_i are also selected according to the MCF principle. Initially, all the pairs of activities (a_i, a_j) , such that ($|R_i| > 1 \vee |R_j| > 1$ and $R_i \cap R_j \neq \emptyset$) undergo a double-key sorting, where the primary key is a heuristic evaluation based on resource flexibility and computed as $F_{ij} = 2(|R_i| + |R_j|) - |R_i \cap R_j|$, while the secondary key is the known $VarEval(a_i, a_j)$ heuristic, based on temporal flexibility⁵. Then, we select the pair (a_i^*, a_j^*) with the lowest value of the pair $\langle F_{ij}, VarEval(a_i, a_j) \rangle$, where $VarEval(a_i, a_j)$ is computed for each possible resource $r \in R_i \cap R_j$. Finally, between x_i^* and x_j^* we select the variable whose domain of values has the lowest cardinality.

Value ordering on the decision variables x_i is also accomplished by using temporal flexibility measures. If R_i

⁴The \sqrt{S} bias is introduced to take into account cases where a first conflict with the overall $\min\{slack(e_i, s_j), slack(e_j, s_i)\}$ has a very large $\max\{slack(e_i, s_j), slack(e_j, s_i)\}$, and a second conflict has two shortest path values just slightly larger than this overall minimum. In such situations, it is not clear which conflict has the least temporal flexibility.

⁵The resource flexibility F_{ij} increases with the size of the domains R_i and R_j , and decreases with the size of the set $R_i \cap R_j$, which is correlated to the possibility of creating resource conflicts.

is the domain of the selected decision variable x_i , then for each resource $r \in R_i$, we consider the set of activities A_r already assigned to resource r and calculate the value $F_{min}(r) = \min_{a_k \in A_r} \{VarEval(a_i, a_k)\}$. Then, for each resource r we evaluate the flexibility associated with the most critical pair (a_i, a_k) , under the hypothesis that the resource r is assigned to a_i . The resource $r^* \in R_i$ which maximizes the value $F_{min}(r)$, and therefore allows a_i to retain maximal flexibility, is selected.

The PCP Algorithm

Figure 1 gives the basic overall PCP solution procedure, which starts from an empty solution (Step 1) where the graphs G_d is initialized according to Section . Also, the procedure accepts a *never-exceed* value (C_{max}) of the objective function of interest, used to impose an initial *global* makespan to all the jobs. The PCP algorithm shown in Figure 1 analyses the decision variables x_i and o_{ijr} , and respectively decides their *values* in terms of imposing a duration constraint on a selected activity or a setup time constraint (i.e., $a_i \preceq a_j$ or $a_j \preceq a_i$, see Section). In broad terms, the procedure in Figure 1 interleaves the application of Dominance Conditions (Steps 4 and 7) with variable and value ordering (Steps 10 and 14 respectively) and updating of the solution graph G_d (Steps 8 and 15) to conduct a single pass through the search tree. At each cycle, a propagation step is performed (Step 3) by the function $\text{Propagate}(S)$, which propagates the effects of posting a new solving decision (i.e., a setup time constraint) in the graph G_d . In particular, $\text{Propagate}(S)$ updates the shortest path distances on the graph G_d . A solution S is found when the PCP algorithm finds a feasible assignment of resources $\bar{r}_i \in R_i$ to activities a_i ($i = 1 \dots n$) and when none of the four dominance conditions is verified on S . In fact, when none of the four Dominance Conditions is verified (and the PCP procedure exits with success), for each resource r , the set of activities A_r assigned

Figure 2: The IFS schema

to r represents a total execution order. In addition, as the graph G_d represents a consistent Simple Temporal Problem (see Section), one possible solution of the problem is the *earliest-time solution*, such that $S = \{(-d(s_1, tp_0), \bar{r}_1), (-d(s_2, tp_0), \bar{r}_2), \dots, (-d(s_n, tp_0), \bar{r}_n)\}$.

The Optimization Metaheuristic

Figure 2 introduces the generic IFS procedure. The algorithm basically alternates relaxation and flattening steps until a better solution is found or a maximal number of iterations is executed. The procedure takes three parameters as input: (1) an initial solution S ; (2) a positive integer $MaxFail$, which specifies the maximum number of consecutive non makespan-improving moves that the algorithm will tolerate before terminating; (3) a parameter γ explained in . After the initialization (Steps 1-2), a solution is repeatedly modified within the while loop (Steps 3-10) by applying the RELAX procedure (as explained in the following section), and the PCP procedure shown in Figure 1 used as flattening step. At each iteration, the RELAX step reintroduces the possibility of resource contention, and the PCP step is called again to restore resource feasibility. In the case a better makespan solution is found (Step 6), the new solution is saved in S_{best} and the *counter* is reset to 0. If no improvement is found within $MaxFail$ moves, the algorithm terminates and returns the best solution found.

Relaxation Procedure

The first part of the IFS cycle is the *relaxation step*, wherein a feasible schedule is relaxed into a possibly resource infeasible, but precedence feasible, schedule by retracting some number of scheduling decisions. Here we use a strategy similar to the one in (Godard, Laborie, and Nuijten 2005) and called *chain-based relaxation*. Given the graph representation described above, each scheduling decision is either a *setup time constraint* between a pair of activities that are competing for the same resource capacity and/or a *resource assignment* to one activity. The strategy starts from a solution S and randomly *breaks* some total orders (or *chains*) imposed on the subset of activities requiring the same resource r . The relaxation strategy requires an input solution as a graph $G_S(A, J, X_S)$ which is a modification of the original precedence graph G that represents the input scheduling

problem. G_S contains a set of additional *general* precedence constraints X_S which can be seen as a set of *chains*. Each chain imposes a total order on a subset of problem activities requiring the same resource.

The *chain-based relaxation* proceeds in two steps. Firstly, a subset of activities a_i is randomly selected from the input solution S , according to some criteria that will be explained below. The selection process is generally driven by a parameter $\gamma \in (0, 1)$ that indicates the probability that each activity has to be selected (γ is called the *relaxing factor*). For each selected activity, the resource assignment is removed and the original set of available options R_i is re-established. Secondly, a procedure similar to CHAINING – used in (Policella et al. 2007) – is applied to the set of unselected activities. This operation is in its turn accomplished in three steps: (1) all previously posted setup time constraints X_S are removed from the solution S ; (2) the unselected activities are sorted by increasing earliest start times of the input solution S ; (3) for each resource r and for each unselected activity a_i assigned to r (according to the increasing order of start times), a_i 's predecessor $p = \text{pred}(a_i, r)$ is considered and the setup time constraint related to the sequence $p \preceq a_i$ is posted (the dummy activity a_0 is the first activity of all the chains). This last step is iterated until all the activities are linked by the correct setup time constraints. Note that this set of unselected activities still represents a feasible solution to a scheduling sub-problem, which is represented as a graph G_S in which the randomly selected activities *float* outside the solution and thus re-create *conflict* in resource usage.

As anticipated above, we implemented two different mechanisms to perform the random activity selection process, respectively called *Random* and a *Slack-based*.

Random selection According to the random selection approach, at each solving cycle of the IFS algorithm in Figure 2, a subset of activities a_i is randomly selected from the input solution S , with each activity having an uniformly distributed selection probability equal to γ . It is of great importance to underscore that according to this approach, the activities to be relaxed are randomly picked up from the solution S with the *same probability* which, as we will see shortly, entails a relaxation characterized by a greater disruption on S , compared to the following selection approach.

Slack-based selection As opposed to the random selection, at each iteration the slack-based selection approach restricts the pool of the relaxable activities to the subset containing those activities that are closer to the *critical path condition* (*critical path set*). As known, an activity a_i belongs to the critical path (i.e., meets the critical path condition) when, given a_i 's end time e_i and its feasibility interval $[lb_i, ub_i]$, the condition $lb_i = ub_i$ holds. For each activity a_i , the smaller the difference $ub_i - lb_i$ (informally called *slack*) computed on e_i , the closer is a_i to the critical path condition. At each IFS iteration the critical path set is built so as to contain any activity a_i with a probability directly proportional to the γ parameter and inversely proportional to a_i 's slack. For ob-

vious reasons, the slack-based relaxation entails a smaller disruption on the solution S , as it operates on a smaller set of activities; the activities characterized by a great slack will have a minimum probability to be selected. As explained in the following section, this difference has important consequences on the experimental behaviour.

Experimental Analysis

The empirical evaluation has been carried out on a SDST-FJSSP benchmark set synthesized on purpose out of the first 20 instances of the *edata* subset of the FJSSP *HUdata* testbed from (Hurink, Jurisch, and Thole 1994), and will therefore be referred to as *SDST-HUdata*. Each one of the *SDST-HUdata* instances has been created by adding to the original *HUdata* instance one Setup-Time matrix $st^r(nJ \times nJ)$ for each present machine r , where nJ is the number of present jobs. The same Setup-Time matrix was added for each machine of all the benchmark instances. Each value $st_{i,j}^r$ in the Setup-Time matrix models the setup time necessary to reconfigure the r -th machine to switch from job i to job j . Note that machine re-configuration times are sequence dependent: setting up a machine to process a product of type j after processing a product of type i can generally take a different amount of time than setting up the same machine for the opposite transition. The elements $st_{i,j}^r$ of the Setup-Time matrix satisfy the *triangle inequality* (Brucker and Thiele 1996; Artigues and Feillet 2008), that is, for each three activities a_i, a_j, a_k requiring the same machine, the inequality $st_{ij}^r \leq st_{ik}^r + st_{kj}^r$ holds. The 20 instances taken from *HUdata* (namely, the instances *la01-la20*) are divided in four groups of five ($nJ \times nA$) instances each, where nJ is the number of jobs and nA is the number of activities per job for each instance. More precisely, group *la01-la05* is (10×5), group *la06-la10* is (15×5), group *la11-la15* is (20×5), and group *la16-la20* is (10×10). In all instances, the processing times on machines assignable to the same activity are identical, as in the original *HUdata* set. The algorithm used for these experiments has been implemented in Java and run on a AMD Phenom II X4 Quad 3.5 Ghz under Linux Ubuntu 10.4.1.

Results. Table 1 and Table 2 show the obtained results running our algorithm on the *SDST-HUdata* set using the *Random* or *Slack-based* procedure in the IFS relaxation step, respectively. Both tables are composed of 10 columns and 23 rows (one row per problem instance plus three data wrap-up rows). The *best* column lists the shortest makespans obtained in the experiments for each instance; underlined values represent the best values obtained from both tables (global bests). The columns labeled $\gamma = 0.2$ to $\gamma = 0.9$ (see Section) contain the results obtained running the IFS procedure with a different value for the *relaxing factor* γ . For each problem instance (i.e., for each row) the values in bold indicate the best makespan found among all the tested γ values (γ runs).

For each γ run, the last three rows of both tables show respectively (up-bottom): (1) the number B of best solutions

One significant result that the tables show is the difference in the average of utilized solving cycles (Av.C. row) between the *random* and the *slack-based* relaxation procedure.

⁶The individual MRE of each solution is computed as follows: $MRE = 100 \times (C_{max} - LB) / LB$, where C_{max} is the solution makespan and LB is the instance's lower bound

In fact, it can be observed that on average the slack-based approach uses more solving cycles in the same allotted time than its random counterpart (i.e., the slack-based relaxation heuristic is faster in the solving process). This is explained by observing that the slack-based relaxation heuristic entails a less severe disruption of the current solution at each solving cycle compared to the random heuristic, as the former generally relaxes a lower number of activities (given the same γ value). The lower the disruption level of the current solution in the relaxation step, the easier it is to re-gain solution feasibility in the flattening step. In addition of this efficiency issue, the slack-based relaxation approach also provides the extra effectiveness deriving from operating in the vicinity of the critical path of the solution, as demonstrated in (Cesta, Oddi, and Smith 2000).

The good performance exhibited by the slack-based heuristic can be also observed by inspecting the *B(N)* rows in both tables. Clearly, the slack-based approach finds a higher number of best solutions (17 against 12), which is confirmed by comparing the number of locally found bests (*B*) with the global ones (*N*), for each γ value, and for both heuristics.

Another interesting aspect can be found analyzing the γ values range where the best performances are obtained (*Av.MRE* row). Inspecting the *Av.MRE* values, the following can in fact be stated: (1) the slack-based heuristic finds solutions of higher quality w.r.t. the random heuristic over the complete γ variability range; (2) in the random case, the best results are obtained in the $[0.3, 0.5]$ γ range, while in the slack-based case the best γ range is wider ($[0.3, 0.6]$).

Conclusions

In this paper we have proposed the use of Iterative Flattening Search (IFS) as a means of effectively solving the SDST-FJSSP. The proposed algorithm uses as its core solving procedure an extended version of the SP-PCP procedure presented in (Oddi and Smith 1997) which introduces a new set of dominance conditions tailored to capture the SDST-FJSSP's features (i.e., alternative activity-resource assignments plus sequence dependent setup times), as well as a new relaxation strategy. The performance of the procedure has been tested on a modified version of a known FJSSP benchmark set (i.e., the Hurink edata), integrated with a series of sequence dependent setup time constraints. The new relaxation strategy has been compared against a fully random version, demonstrating a noteworthy improvement in performance. To the best of our knowledge, no similar works exist on the same problem version to allow direct comparison with different approaches. The benchmark used in this analysis will be made available on the net so as to facilitate experiment reproducibility and encourage research competition.
